Paroxysmal nocturnal haemoglobinuria (PNH) is an acquired disorder of the haematopoietic stem cell that makes blood cells more sensitive to the action of complement. PNH patients experience an increased risk of arterial and venous thrombosis – major causes of death due to this disease. Though many potential interlaced mechanisms are suspected, extracellular vesicles (EVs) of various origins may play a central role. The processes possibly involved are haemolysis, platelet activation, injured endothelial cells and monocyte activation. The impact of transfusion should be evaluated. A better understanding of the mechanisms involved may help to propose guidelines for the prophylaxis and treatment of thrombosis in PNH. In this paper, we propose an updated review of the pathophysiology of the underlying mechanisms of thrombosis associated with PNH, with specific focus on the prominent role of EVs.

Keywords: *haemoglobinuria; thrombosis; complement; extracellular vesicles; transfusion*

Paroxysmal nocturnal haemoglobinuria (PNH) is a rare, acquired disorder of the pluripotent haematopoietic stem cell and therefore can affect erythrocytes, leukocytes, thrombocytes (1) and probably some endothelial cells too (2). These haematopoietic stem cells have acquired a somatic mutation in an X-linked gene: the phosphatidylinositol glycan class A (PIG-A). This gene is required for the synthesis of the glycosylphosphatidylinositol (GPI) anchor, which is necessary to attach some proteins to the cell membrane.

The lack of synthesis of the GPI anchor leads to the under-expression of a variety of proteins on the haematopoietic stem cell surface and on all cell lines that are generated by it. By this mechanism, lack of 2 important complement regulators is observed on the cell surface: “decay accelerating factor” (DAF), recognized by antibody CD55, and “membrane inhibitor of reactive lysis” (MIRL), recognized by antibody CD59. Consequently, red blood cells are more vulnerable to the action of complement, leading to complement-mediated intravascular

haemolysis (see Fig. 1) (3). As a result, a high concentration of free haemoglobin is found in the plasma, responsible for nitric oxide (NO) scavenging. NO depletion causes smooth muscle dystonia, responsible for dysphagia and abdominal pain. NO depletion may also contribute to the development of arterial constriction, leading to reduced blood flow to the kidneys (with renal failure), arterial hypertension and pulmonary hypertension (associated with frequent but under-diagnosed pulmonary embolism) (4).

Management and treatment of classic PNH has been dramatically revolutionized by the development of eculizumab (Soliris[®] by Alexion Pharmaceuticals) and its approval in 2007 by the US FDA and the European Union Commission. This humanized monoclonal antibody blocks the activation of terminal complement C5 and prevents the formation of C5a and C5b-9, preventing haemolysis. Several beneficial effects of eculizumab have been demonstrated, in terms of haemolysis, quality of life (5,6), renal function (7) and life expectancy (8).

Fig. 1. Action of complement in healthy subjects (A) and PNH patients (B). (A) Due to the presence of membrane proteins, DAF and MIRL, a normal RBC is protected from complement activation. (B) DAF and MIRL deficiency makes the RBC sensitive to complement attack, resulting in haemolysis. RBC = red blood cells, MAC = membrane attack complex.

A reduction in the incidence rate of thromboembolic events (9) and a decrease in markers of thrombin generation (10,11) were also observed during eculizumab therapy. The mechanisms involved, however, remain misunderstood.

Thrombosis in PNH

Clinical characteristics

Thrombotic events occur in 40% of PNH patients and represent the major cause of death due to this disease. Indeed, 40–67% of PNH patients will die of thrombotic complications. An initial thrombotic event increases the relative risk of death by 5- to 10-fold (12). Understanding,

anticipating and treating thrombosis represent a major challenge in PNH.

Thrombotic events are of venous origin in 85% of the cases but arterial thrombosis is not so rare (15%) (4). Thrombotic events (20.5%) involve more than 1 site at the same time. Thrombosis not only affects usual sites such as deep veins of the lower limbs, pulmonary arteries, coronary arteries or central nervous system (CNS) arteries but also, more typically, unusual sites such as hepatic veins (Budd-Chiari syndrome: 40.7–44.0% of PNH patients with thrombosis (12)), cavernous sinus, CNS veins, mesenteric veins or dermal veins (13).

In PNH patients, the age of onset of thrombosis is lower than among the general population (46 years vs.

73 years) (4). An increased risk of thrombosis was reported among African American or Latin American PNH patients compared with other PNH patients (14). A lower risk was reported among Chinese and Japanese PNH patients (12). The mechanism is still unknown.

Recurrences of thrombosis despite antithrombotic therapy (warfarin, unfractionated heparin, enoxaparin, aspirin, tirofiban) have been described (15,16).

Thrombosis during pregnancy and post-partum seems particularly frequent. Indeed, a maternal mortality of 20% and a perinatal mortality of 10% have been reported, mostly due to thrombosis. Consequently, some authors do not recommend pregnancy in patients suffering from PNH (13).

The role of EVs

The exact pathophysiology of this hypercoagulable state in PNH is unknown but may be multifactorial, as illustrated in Fig. 2. Extracellular vesicles (EVs) are sub-micron-size cellular fragments released by eukaryotic cells (including platelets, leukocytes, endothelial cells and red blood cells) following activation or apoptosis. They are highly heterogeneous both in size (30–1,000 nm) and in composition. EVs are complex and ambivalent structures that not only express both activators and inhibitors of coagulation but also convey fibrinolytic properties. They are therefore considered as the main regulator of the balance between coagulation and fibrinolysis. They play a major role in cellular cross-talk, inflammation, haemostasis and thrombosis (17–19).

It was demonstrated *in vitro* that platelet EVs have from 50 to 100-times higher pro-coagulant activity than platelets (20). Indeed, an inherited defect of lipid scramblase is seen in Scott's syndrome, a rare autosomal recessive disease. This leads to reduced production of EVs, causing severe bleeding (21–23).

EVs are known to expose phosphatidylserine on their surface, providing a support for the assembly of the pro-coagulant enzyme complexes – prothrombinase and tenase (21,22,24).

Tissue factor, the principal initiator of coagulation, is also exposed on the surface of some EVs. More and more evidences suggest that EVs are the main carriers of circulating tissue factor (TF) and, thereby, may contribute to normal coagulation (25). However, TF activity of EVs from non-stimulated blood was not detectable in most studies (26). Monocytes are thought to be the only blood cells that synthesize TF *in vivo*. TF is constitutively expressed in an encrypted form in monocytes but may be decrypted during cell activation. Indeed, monocyte's TF mRNA levels are increased after stimulation (26). Some authors speculate that TF expressed on cholesterol-rich lipid rafts on monocyte-derived EVs may take part in the link between hypercholesterolemia and thrombosis (27). The role of EV-associated TF in haemostasis is not extensively discussed here because it has been well covered in other reviews (24,28,29) and is still under study. The synergies of phosphatidylserine and protein disulphide isomerase as well as the recycling by endothelial cells have been recently demonstrated as important

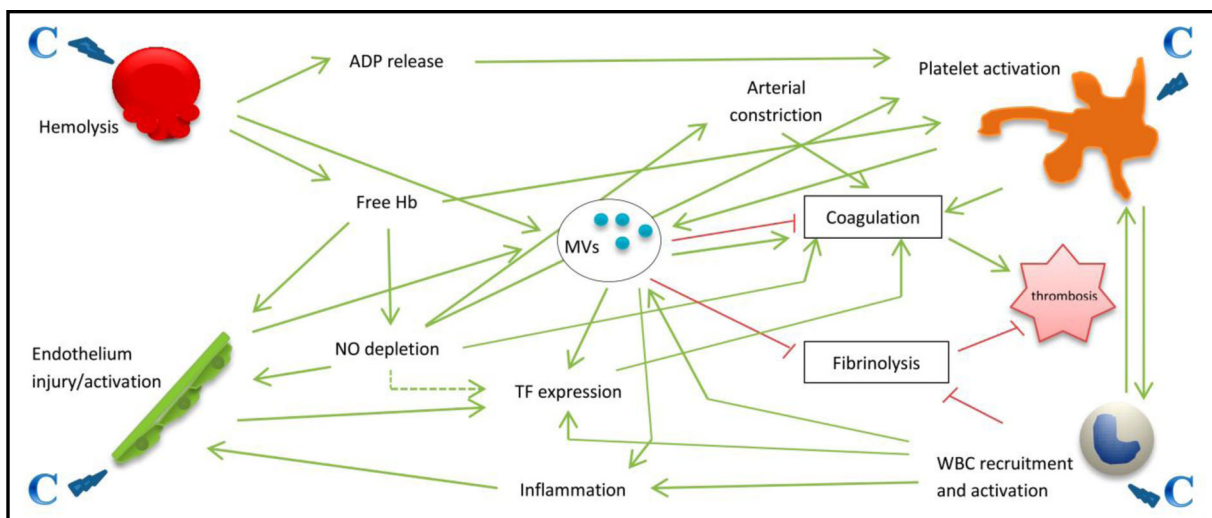

Fig. 2. Overview of the multiple mechanisms involved in the occurrence of thrombosis in PNH patients. Complement (C) activation is responsible of haemolysis, platelet activation, endothelium injury and activation, and white blood cell (WBC) recruitment and activation. From there, multiple mechanisms induce a hypercoagulable state with the occurrence of thrombosis. Note the central role of extracellular vesicles (or microvesicles: MVs). ADP = adenosine diphosphate, Hb = haemoglobin, NO = nitric oxide, TF = tissue factor.

in tissue factor activation (30,31). In addition, contrary to what was believed before, very small TF-bearing EVs (< 100 nm) may have a pro-coagulant effect, especially in the presence of phospholipids (32,33).

In PNH, complement activation at the cell surface of GPI-deficient cells may stimulate the release of pro-coagulant EVs. Indeed, increased levels of circulating EVs have been measured in PNH patients, a majority of them coming from platelets. Yet, no correlation between the clone size and the number of EVs could be demonstrated (34). One study (35) showed increased plasmatic levels of TF antigen (measured by ELISA, after adjunction of triton) in 2 PNH patients suffering from recurrent thrombotic complications, compared to normal controls.

The role of platelet activation

Platelet membranes of PNH patients are deficient in DAF (CD55) and MIRL (CD59). It is known that complement does not directly destroy platelets but is able to induce platelet activation. Therefore, complement may induce platelet activation and vesiculation in an insufficiently regulated manner in PNH patients. Indeed, it has been found that PNH platelets, after membrane attack complex (MAC) stimulation, expose more activated factor five-binding sites and increase thrombin generation more than that of normal platelets (36). One study also showed increased adherence of platelets to the abdominal vessels in PNH. This interesting feature could partly explain the particular occurrence of mesenteric vein thrombosis in these patients and suggest a peculiar mechanism involving the special distribution of a hypercoagulable state in these patients (4). In contrast, other studies showed impaired function of PNH platelets as a result of a reactive down-regulation in response to their chronic hyperstimulation (36).

The number of platelet extracellular vesicles (PEVs) is sometimes used as a marker of platelet activation (37) and may be of particular interest in PNH. Nowadays, it is still very difficult to find a reliable plasma marker of platelet activation. P-selectin, β -thromboglobulin, platelet factor 4 (PF4) and thromboxane B2 have been studied in physiological and pathological states but all these have limitations (38,39). The ideal candidate should be a specific marker of platelet, resistant to the artefacts of venipuncture and collection and not influenced by antithrombotic drugs. It should be measured according to a cheap, simple and reproducible operating procedure (38). Further research needs to be done in this field.

The controversial impact of haemolysis

Haemolysis has long been considered as a major contributor of thrombosis, but its role is now controversial. NO depletion can cause arterial constriction and thus play a role in arterial thrombosis, but veins do not have smooth muscle. Platelet activation may be increased by the lack of NO (4) and by the release of adenosine diphosphate

(ADP) (40) in case of haemolysis. The impact of NO depletion in an increase of TF expression is controversial. However, no link can be made between severity of haemolysis and thrombosis or severity of anaemia and thrombosis (4). One study showed that human red blood cell stroma is capable of activating the alternate complement pathway *in vitro*. The ensuing interaction of activated complement components with platelets may lead to activation of the coagulation system (41).

Similar levels of red blood cells-derived EVs (REVs) were found in PNH patients or healthy controls, but *in vitro* experiments showed that PNH erythrocytes release higher amounts of pro-coagulant EVs upon complement stimulation (42). This may suggest a rapid clearance of erythrocyte EVs from the circulation (36). We know that vesicles are partly cleared by a scavenging receptor on the monocytes, which can induce monocyte TF expression, promoting coagulation. In turn, monocytes, after complement damage, can release EVs that contain TF. These EVs may be captured by endothelial cells, increasing their own TF expression (4,31).

Injured endothelial cells

Endothelial EV levels are also increased in PNH patients, showing a pro-inflammatory and pro-thrombotic phenotype (43). The endothelial cells probably play an important role in the pathophysiology of thrombosis in PNH. Endothelial cells suffer from direct toxicity of free haemoglobin released (44) but may also be particularly sensitive to the action of complement. It has been shown that endothelial precursor cells may be bone marrow-derived cells (2). They would then be deficient in GPI-anchored proteins, making them more susceptible to complement injury. This would be of particular importance for the development of thrombosis in unusual sites (4). Increased levels of endothelial cell activation markers, such as von Willebrand factor (VWF) or soluble vascular cell adhesion molecule-1 (sVCAM-1), are observed in PNH (11).

The effect of complement on other cell lines

Complement injury to other cell lines can also contribute to thrombosis in PNH. Complement protein C5a binds to a receptor on granulocytes and enhances recruitment and activation of granulocytes and monocytes. This molecule is considered as a possible link between inflammation and thrombosis (45). In GPI-deficient white blood cells, this mechanism may be intensified and may lead to an important release of inflammatory molecules and EVs. This inflammatory process induces damages to the endothelium and enhances TF expression, which initiates the coagulation cascade (4). It seems clear that complement and coagulation systems are closely intertwined. This has been reinforced by the fact that thrombin by itself is able to initiate the alternative pathway of complement (46).

Tissue factor pathway inhibitor deficiency

Tissue factor pathway inhibitor (TFPI) normally limits coagulation initiation by inhibiting TF formation. It is mainly produced by the endothelium of the microvasculature and is bound to a GPI-anchored protein. Therefore, it lacks in PNH. In previous studies, loss of TFPI expression has been associated with an increased risk of thrombosis (4). In addition, a decrease of TFPI expression on circulating EVs has been observed in certain clinical situations and may induce thrombin generation due to unopposed TF activity (47). This could play a role in thrombosis in PNH.

Lack of other GPI-anchored proteins

As we have already discussed, the lack of several GPI-anchored proteins at the cell surface may lead to altered coagulation. The GPI-anchors' deficit may also interfere with coagulation in an indirect manner. For example, neutrophil proteinase-3 (PR-3) is a membrane-bound protein, which is co-localized with GPI-anchored neutrophil antigen 2a. The lack of neutrophil antigen 2a in PNH leads to loss of expression of PR-3. However, PAR-1, the predominant human platelet thrombin receptor, is a substrate for PR-3. It has been shown that impaired down-regulation of PAR-1 leads to an increased propensity for platelet activation. PR-3 also modulates coagulation in various other ways (48).

Congenital and acquired thrombophilia

Frequency of congenital thrombophilia factors (Factor V Leiden, antithrombin deficiency, protein C or S deficiency, prothrombin mutations, hyperhomocysteinaemia and methylenetetrahydrofolate reductase mutations) is not increased in PNH. Testing for such factors may identify PNH patients at additional thrombotic risk, but its value for treatment decision in PNH is still unknown (36). A higher rate of antiphospholipid antibodies was found in PNH patients than in healthy volunteers (49). This could be a contributory factor for thrombosis in PNH.

In addition, Grünewald et al. (50) have studied various markers of coagulation in PNH and noted a significant increase in pro-coagulant factor activities (factor V, fibrinogen, factor VIII, factor IX, factor X and VWF), with a positive correlation with clone size.

Impaired and/or increased fibrinolysis

About fibrinolysis in PNH, the results of various studies are conflicting. The role of urokinase-type plasminogen activator receptor (u-PAR) may however be important. U-PAR, a GPI-linked protein expressed on neutrophils, plays a central role in the regulation of haemostatic processes on cell surface. Indeed, the binding of urokinase-type plasminogen activator (u-PA) to u-PAR converts plasminogen into plasmin, mediating endogenous thrombolysis. This proteolytic activity is spatially restricted to the plasma

membrane (51). In PNH, studies have shown that u-PAR is under-expressed on the cellular surface of leukocytes and platelets and also that concentration of soluble u-PAR is increased in plasma of PNH patients. Furthermore, serum-soluble u-PAR concentrations correlated with PNH granulocyte clone size and were the highest in patients who later developed thrombosis (52). They hypothesize that u-PAR is released from PNH haematopoietic cells to plasma (53). This would be the responsibility of an impaired and displaced fibrinolytic system in PNH.

Other fibrinolytic parameters have been studied, some of them suggesting an increased activity of the fibrinolytic system in PNH. Indeed, elevated levels of d-dimers and of complexes of plasmin and plasmin inhibitors were found, as was the case for complexes of tissue-type plasminogen activator (t-PA) and its inhibitor (PAI-1). However, an inverse association with clone size was described and correlations were weak (50).

In healthy subjects and in several pathological conditions, it is now suspected that EVs have a fibrinolytic activity (18). The exposure of u-PA or t-PA and their receptor (u-PAR and annexin II) was demonstrated on the surface of EVs from various origins (54–58). Their impact on fibrinolysis in PNH patients remains to be studied.

The impact of transfusions

PNH patients who receive frequent transfusions of red blood cells may have a further increased risk of thrombosis. Indeed, the use of transfusion was isolated as an independent risk factor for thrombosis in PNH (15). Unfortunately there is no prospective study that quantifies the level of this risk.

An exogenous source of PEVs or REVs in PNH could be constituted by transfusion. Indeed, patients suffering from PNH frequently need red blood cell or platelet transfusions. Anaemia induced by haemolysis is not, in this situation, a contraindication for red blood cell transfusion. On the contrary, receiving allogeneic red blood cells (in which the membrane is not GPI deficient) is good enough to limit the stimulation of erythropoiesis, decrease the production of deficient red blood cells and thus lessen haemolysis and its symptoms. Red blood cell or platelet transfusions are also required when PNH is associated with a bone marrow failure syndrome (3). PNH patients, receiving frequent transfusions of red blood cells, may have a further increased risk of thrombosis. Indeed, the use of transfusion was isolated as an independent risk factor for thrombosis in PNH (15). However, there is no prospective study that quantifies this risk.

Regardless of PNH, lots of observations suggest that red blood cell transfusion is associated with increased thrombotic events and mortality. Indeed, blood transfusion in the setting of acute coronary syndromes was associated with higher mortality (OR 3.94) (59). Khorana

et al. (60) observed that red blood cell transfusion was independently associated with an increased risk of venous (OR 1.60) and arterial (OR 1.53) thrombotic events and mortality (OR 1.34) in hospitalized cancer patients. Similarly, Abu-Rustum et al. (61) demonstrated an association between transfusion and increased risk of thrombotic events in women during adnexal or peritoneal cancer surgery (OR 4.80), and Nilsson et al. (62) observed that perioperative blood transfusion was associated with an increased risk of venous thromboembolism in women undergoing colorectal cancer resection (OR 1.80). More recently, an increase in perioperative graft thrombosis was observed in patients transfused during a surgery of lower extremity bypass (OR 2.10 to 4.80, depending on the number of units transfused) (63). Kumar et al. (64) also demonstrated that red blood cell transfusion was associated with an increased risk of thrombotic events in patients with subarachnoid haemorrhage (OR 2.40).

The mechanisms that underlie these findings remain unclear. It is known that red blood cell transfusions alter viscosity by both raising haematocrit and by introducing erythrocytes with altered viscoelastic properties into the circulation (62). This could increase the risk of thrombosis. Increasing the circulating red cell mass may also improve haemostasis (60). The depletion of NO in stored red blood cells may promote vasoconstriction and platelet aggregation (59). The delivery of redox-active iron and pro-inflammatory mediators by transfusion may also play a role (60).

In addition, the delivery of pro-coagulant EVs contained in the transfused product may be able to promote haemostasis and increase the risk of thrombosis. Indeed, it has been observed that the number of EVs contained in packed red blood cells increases during storage (65) and that red blood cells-derived EVs isolated from blood units are capable of initiating and propagating thrombin generation (65). Moreover, duration of red blood cell storage was associated with increased incidence of deep vein thrombosis in patients with traumatic injuries in a retrospective cohort study (66).

Risk factors for thrombosis

A previous history of thrombosis and a large white blood cell clone are well-known risk factors for thrombosis in PNH (67). Indeed, a 10-year cumulative incidence of thrombosis of 34.5% is observed in patients having a large clone (> 50%), compared with 5.3% in patients with a smaller clone (< 50%) (40). The risk of thromboembolic events increases by 1.64-fold for every 10% increase in the size of the white blood cell clone (12). Age more than 55 years and the use of transfusion were also isolated as independent risk factors for a first thrombotic event (15). Ethnicity seems to be another risk factor for thrombosis as discussed above (14). The elevation of

D-dimers has also been associated with an increased thrombotic risk in PNH (4).

Conclusion

Even if the management of PNH has been dramatically revolutionized by the development of eculizumab, prevention and treatment of thrombotic complications remain a challenge.

A better understanding of the underlying pathophysiologic mechanisms of thrombosis in PNH should allow us to identify new potential biomarkers of thrombosis, such as EVs.

More and more studies have indicated a potential role of EVs in thrombosis associated with PNH. However, published data were produced using low-sensitive and not standardized flow cytometry. But progress has been performed in the field of flow cytometry (68–71). Therefore, the role of EVs should be investigated using high-sensitive and standardized techniques. Moreover, as the research focused on the pro-coagulant function of EVs, its function in fibrinolysis should also be studied in the near future.

The ultimate goal is to propose guidelines for prophylaxis and treatment of thrombosis associated with PNH. Moreover, the impact of transfusion on thrombotic risk deserves to be further studied.
