21 **Abstract**

22 Current chemical risk assessment approaches rely on a standard suite of test species to assess
23 toxicity to environmental species. Assessment factors are used to extrapolate from single
24 species to communities and ecosystem effects. This approach is pragmatic, but lacks
25 resolution in biological and environmental parameters. Novel modelling approaches can help
26 improve the biological resolution of assessments by using mechanistic information to identify
27 priority species and priority regions that are potentially most impacted by chemical stressors.
28 In this study we developed predictive sensitivity models by combining species-specific
29 information on acute chemical sensitivity (LC50 and EC50), traits, and taxonomic
30 relatedness. These models were applied at two spatial scales to reveal spatial differences in
31 the sensitivity of species assemblages towards two chemical modes of action (MOA): narcosis
32 and acetylcholinesterase (AChE) inhibition. We found that on a relative scale, 46% and 33%
33 of European species were ranked as more sensitive towards narcosis and AChE inhibition,
34 respectively. These more sensitive species were distributed with higher occurrences in the
35 south and north-eastern regions, reflecting known continental patterns of endemic
36 macroinvertebrate biodiversity. We found contradicting sensitivity patterns depending on the
37 MOA for UK scenarios, with more species displaying relative sensitivity to narcotic MOA in
38 north and north-western regions, and more species with relative sensitivity to AChE inhibition
39 MOA in south and south-western regions. Overall, we identified hotspots of species sensitive
40 to chemical stressors at two spatial scales, and discuss data gaps and crucial technological
41 advances required for the successful application of the proposed methodology to invertebrate
42 scenarios, which remain underrepresented in global conservation priorities.

43 **1. Introduction**

44 The scientific community is rapidly developing new ecological models to increase realism in
45 environmental risk assessment (ERA, e.g. De Laender, Morselli, Baveco, Van den Brink, &
46 Di Guardo, 2015; Windsor, Ormerod, & Tyler, 2018). However, what so far has remained
47 unclear is which organisms need to be modelled. Common standard test species are usually
48 not representative of all species present in ecosystems with regards to their sensitivity to
49 stressors (Nagai, 2016). Indeed, it has already been argued for over 30 years that there is not a
50 single species or a specific group of species which is always the most sensitive (all the time,
51 everywhere, and towards every compound). This has been coined the ‘myth of the most
52 sensitive species’ (Cairns, 1986). However, since in reality both compound multiplicity as
53 well as species diversity occur simultaneously, it is not feasible to acquire all possible
54 sensitivity data with laboratory toxicity testing. Therefore, there is a need to develop models
55 that can help identify priority species, which are species that are likely to be intrinsically most
56 sensitive to chemical stressors.

57 Several studies have tried to determine which species are intrinsically most sensitive to
58 chemical stressors by using species traits, and were able to explain up to 87 percent of the
59 variation in species sensitivity using only four traits (Rico & Van den Brink, 2015; Rubach et
60 al., 2012; Rubach, Baird, & Van den Brink, 2010; van den Berg et al., 2019). A large
61 advantage of using traits-based approaches is that they add mechanistic understanding of the
62 sensitivity process by describing characteristics that make a species more or less sensitive
63 towards chemical stressors. This largely reduces the chances of overfitting models to the
64 training data (Johnson & Omland, 2004). In addition to that, describing aquatic communities
65 in terms of their biological traits increases the generality of such characterizations and their
66 subsequent transferability between regions (Van den Brink et al., 2011). Also, correlations

67 between species traits and species sensitivity might exist, potentially resulting in unexpected
68 effects at the community level (Baert, De Laender, & Janssen, 2017).

69 Other studies (Malaj, Guénard, Schäfer, & Van der Ohe, 2016) concerned with determining
70 which species were most sensitive to chemical stressors, combined phylogenetic information
71 with chemical properties. They were to a great extent (R^2 of ~ 0.8) capable of predicting
72 species sensitivity to pesticides (Guénard, von der Ohe, Walker, Lek, & Legendre, 2014) and
73 heavy metals (Malaj et al., 2016). Furthermore, some studies have demonstrated that indeed
74 traits and phylogeny (or other measures of relatedness between species) both explain an
75 unique part of the sensitivity process (Pilière et al., 2016; Poteat, Jacobus, & Buchwalter,
76 2015). However, phylogenetic approaches do not unravel any concrete mechanisms of
77 sensitivity, and are therefore more susceptible to overfitting on the training data. For this
78 reason, we think that a combination of both traits and phylogenetic information has the most
79 potential for identifying priority species at a large spatial scale.

80 We envision these priority species to, in the future, become part of environmental scenarios, a
81 simplified (model) representation of exposed aquatic ecosystems which provides a sufficient
82 amount of ecological realism, enabling us to conduct an appropriate ERA (Rico, Van den
83 Brink, Gylstra, Focks, & Brock, 2016). There are clear benefits associated with the
84 development of scenarios for use in risk assessment, the most important ones being reduction
85 of animal tests, integration of exposure and effect assessments, and increased realism with
86 respect to spatial-temporal dimensions and species biodiversity (Rohr, Salice, & Nisbet,
87 2016). However, for obtaining more realism in respect to spatial-temporal dimensions and
88 biodiversity, we require not only the identification of priority species, but also the spatial-
89 temporal dimensions at which these species occur. Therefore, after identifying priority
90 species, looking into the distribution patterns of these species can help to identify priority
91 regions, that is, regions where these priority species are more abundant. These regions can

92 assist in delivering realistic ranges of important landscape parameters (e.g. temperature,
93 discharge, alkalinity) as input for environmental scenarios, enabling more realistic landscape
94 level ERA (Franco et al., 2016; Rico et al., 2016). Additionally, these regions can become the
95 focus of conservation and management efforts.

96 The two main objectives of the present study therefore are i) to construct models predicting
97 the sensitivity of aquatic macroinvertebrates based on mode of action (MOA), traits and
98 relatedness, and ii) to reveal spatial differences in the sensitivity of species composition
99 assemblages by applying the developed models at the continental and national scale. The
100 community composition of European freshwater ecoregions (ERs, based on Illies, 1978) is
101 used for the application of our models at the continental scale, while the reference database of
102 the RIVPACS (River InVertebrate Prediction And Classification System) tool is used for
103 river-type scale within the United Kingdom (Wright, 1994). We conduct the first trait-based
104 chemical sensitivity assessment of freshwater macroinvertebrate assemblages, extensively test
105 the influence of spatial scale on sensitivity patterns, and provide key recommendations for its
106 robust application in data-poor taxa.

107 **2. Methods**

108 The whole methodology of this study has been developed in R, a free software environment
109 (R Core Team, 2018). The R project, along with all scripts and data necessary to reproduce
110 the models and figures performed in this study are available at Figshare
111 ([10.6084/m9.figshare.11294450](https://www.figshare.com/projects/10.6084/m9.figshare.11294450)) (van den Berg, 2019).

112 2.1. Modelling approach

113 We extracted toxicological data from Van den Berg et al. (2019; original data from ECOTOX
114 (USEPA, 2017)), which comprised Mode Specific Sensitivity (MSS) values for 36 and 32
115 macroinvertebrate genera towards baseline (narcosis) and AChE inhibiting toxicants

116 respectively. Briefly, the MSS value represents the average relative sensitivity of each species
117 to a group of chemicals with the same MOA (original MOA classification from Barron,
118 Lilavois, & Martin, 2015), where an MSS value below zero indicates that the species is more
119 sensitive than average, and an MSS value above zero indicates that the species is less
120 sensitive than average. The MOAs narcosis and AChE inhibition were selected for this study,
121 because they were the most data rich (van den Berg et al., 2019). Narcosis, also called
122 baseline toxicity, is found toxic at similar internal concentration across all organisms (Escher
123 & Hermens, 2002; Wezel & Opperhuizen, 1995). Therefore, differences in sensitivity for this
124 MOA are expected to be small, equally distributed across taxonomic groups, and mainly
125 explained by traits related to toxicokinetics (i.e. uptake, biotransformation, and elimination).
126 AChE inhibition is a more specific MOA, and therefore shows large differences in effect
127 concentrations depending on taxonomic group (van den Berg et al., 2019). For this MOA we,
128 therefore, expect a stronger phylogenetic signal. To justify a separate analysis for the two
129 MOAs, we made a correlation plot of the measured MSS values of species that were tested on
130 both MOAs (Figure A.7). The lack of a significant relationship between species sensitivity
131 towards the two MOAs indicates that sensitivity towards them is independent. We therefore
132 chose to perform a separate analysis for both MOAs in this study.

133 The dataset from Van den Berg et al. (2019) also contained data on genus name, unique
134 identifier (UID from the NCBI database, Benson, Karsch-Mizrachi, Lipman, Ostell, & Sayers,
135 2009; Sayers et al., 2009), and traits (original data from Tachet, Richoux, Bournaud, &
136 Usseglio-Polatera, 2000; Usseglio-Polatera, Bournaud, Richoux, & Tachet, 2000). In this
137 study, we added relatedness to this dataset by constructing a taxonomic tree, since detailed
138 phylogenetic data was still largely unavailable or incoherent for most freshwater
139 macroinvertebrates (we looked, for instance, in Genbank, Benson et al., 2009), and Guénard
140 and Von der Ohe et al. (2014) have provided sufficient proof that taxonomic relatedness

141 explains around the same amount of variation in species sensitivity as phylogenetic data when
142 a wide taxonomic range is taken into consideration. This taxonomic tree is subsequently
143 converted to Phylogenetic Eigenvector Maps (PEMs), from which species scores are extracted
144 which subsequently serve as predictors of relatedness in model construction (Griffith & Peres-
145 Neto, 2006; Guénard, Legendre, & Peres-Neto, 2013).

146 2.1.1. Constructing the taxonomic tree.

147 We constructed the taxonomic tree by extracting taxonomic data from the NCBI (National
148 Centre for Biotechnology Information) database (Benson et al., 2009; Sayers et al., 2009),
149 followed by applying the *class2tree* function from the **taxize** package in R (version 0.9.3,
150 Chamberlain & Szöcs, 2013). Both the model species (for which we had sensitivity data
151 available) and the target species (whose sensitivity we wanted to predict) were included in the
152 tree. The simultaneous incorporation of both model and target species was necessary, because
153 the PEM would change if the large number of target species would be added to the tree at a
154 later point.

155 2.1.2. Phylogenetic eigenvector maps.

156 As descriptors of the taxonomic tree, phylogenetic eigenvectors were obtained from the PEM
157 (see Guénard et al., 2013 for details). PEMs work on a similar basis as principal component
158 analysis (PCA; Legendre & Legendre, 2012). Briefly, the eigenvectors of a PEM are obtained
159 from a decomposition of the among-species covariance's and represent a set of candidate
160 patterns of taxonomic variation of the response variables (i.e. the sensitivities to different
161 chemicals). As is the case for a traditional PCA, this decomposition results in $n - 1$
162 eigenvectors (Legendre & Legendre, 2012), where in our analysis n was the number of model
163 species. The calculation of a PEM is obtained from both the structure of the taxonomic tree
164 and from the dynamics of the (in our case) sensitivity evolution. The dynamics of the

165 sensitivity evolution depends on the strength of a steepness parameter (parameter α ; related to
166 Pagels' parameter κ (Pagel, 1999), where $\alpha = 1 - \kappa$). This parameter represents the relative
167 evolution rate of the sensitivity to the MOA, takes values between 0 (natural evolution) and 1
168 (strong natural selection), and was in our study estimated from the known sensitivity of the
169 model species. We constructed the PEMs with the **MPSEM** package (version 0.3-4, Guénard,
170 2018; Guénard et al., 2013).

171 2.1.3. Model construction.

172 For the narcosis dataset, two leverage points were discovered during the modelling process
173 (Figure A.1 and A.2). Since we doubted the validity of these points (they were exactly
174 identical) and were unable to assess their validity (there was no data available on closely
175 related species, and the reference was inaccessible), they were removed from the dataset,
176 reducing the number of species for which toxicity data was available to 34. For the AChE
177 inhibition dataset, only the 27 Arthropoda species present in the dataset were included in the
178 analysis, because this MOA works in a more specific manner, making differences in MOA
179 among different phyla more likely (Maltby, Blake, Brock, & Van den Brink, 2005).

180 Eventually, 33 and 26 eigenvectors were included as taxonomic predictors for narcosis and
181 AChE inhibition respectively (in the modelling process, taxonomic predictors were indicated
182 with a 'V', see Figures A.3 and A.4 for examples of such predictors), and were added to the
183 sensitivity and trait data. To reduce the number of predictors going into the final model
184 building process (required due to memory limitations of the algorithm), an exhaustive search
185 was performed using the *regsubsets* function from the **leaps** package (version 3.0, Lumley &
186 Miller, 2017). From this, traits or phylogenetic eigenvectors that were least frequently
187 included in the best 1% of the models, ordered according to the Bayesian Information
188 Criterion (BIC), were removed from the analysis. Next, an exhaustive regression was
189 performed between the remaining predictors and the available MSS values, allowing a

190 maximum of 4 predictors in the models. The best model was the model with the lowest AICc
191 (Aikaike's Information Criterion with a correction for small sample size, Johnson & Omland,
192 2004). The modelling exercise was repeated using only traits-, and a combination of traits-
193 and taxonomic- predictors. We did not consider taxonomy-only models, because we were
194 primarily interested in obtaining more mechanistic understanding of the sensitivity process.

195 2.2. Predicting unknown taxa

196 The best model found for narcosis and the best model found for AChE inhibition were
197 subsequently applied to the prediction of the sensitivity of species composition assemblages at
198 two different spatial scales, continental and national. For the continental scale, the community
199 composition of European freshwater ecoregions (ERs) was downloaded from
200 <https://www.freshwaterecology.info/> (Schmidt-Kloiber & Hering, 2015). Although we realize
201 that these data do not exactly resemble species assemblage data, it was the only dataset
202 currently available at this spatial scale. For the national scale, the reference database of the
203 RIVPACS tool was downloaded from the website of the Centre for Ecology and Hydrology
204 (<https://www.ceh.ac.uk/services/rivpacs-reference-database>). The RIVPAC database was
205 selected, because it is the only easily accessible database that provides detailed community
206 level data at this spatial scale. The database contains macroinvertebrate assemblages at 685
207 reference sites, and was originally used to assess the ecological quality of UK rivers under the
208 Water Framework Directive. To assess the ecological quality, the 685 sites have in an earlier
209 study been grouped into 43 end groups based on biological and environmental variables
210 (Davy-Bowker et al., 2008). For descriptive summary purposes, these 43 end-groups were
211 furthermore combined into 7 higher level super-groups (Davy-Bowker et al., 2008, Table 1),
212 such that these super-groups can be considered river-types at a relatively broad scale. In this
213 study, we will use the super-groups to assess differences in species sensitivity on a river-type
214 scale (Table 1).

215 The Tachet database was used as a source of traits data (Tachet et al., 2000; Usseglio-Polatera
216 et al., 2000). In order to make species-traits matching between the two community
217 compositions (ERs and RIVPACS) and the Tachet database possible, the taxonomy of the
218 three databases was aligned with the NCBI database using the **taxize** package (version 0.9.3,
219 Chamberlain & Szöcs, 2013). Species from the ER and RIVPACS communities could then be
220 matched with traits from the Tachet database using the UIDs from the NCBI database. This
221 matching was done at genus level. Since the traits in the Tachet database are coded using a
222 fuzzy coding approach (describing a species by its affinity to several trait modalities, see
223 Chevenet, Dolédec, & Chessel, 1994 for more information), a transformation was required
224 before this data could be used. Continuous traits were transformed using a weighted averaging
225 of the different trait modalities, whilst for factorial traits the modality for which the species
226 had the highest affinity was selected (as in van den Berg et al., 2019).

227 At this point, taxonomic and trait data of all the target species (species for which we want to
228 predict sensitivity) were complete, and PEM scores had to be added. To do this, the locations
229 of the target species were extracted from the taxonomic tree, and subsequently transformed
230 into PEM scores using the **MPSEM** package (version 0.3-4, Guénard, 2018; Guénard et al.,
231 2013). The PEM scores were then combined with the traits data, which allowed us to predict
232 the sensitivity (MSS values) towards narcotic and AChE inhibiting chemicals using the two
233 best models developed earlier.

234 The sensitivity of each ER or river type was determined by calculating the percentage of
235 species with an MSS value below 0, comparable to (Hering et al., 2009). For RIVPACS, this
236 was initially done both on abundance and presence-absence data, on the seasons spring,
237 summer and autumn separately, and averaged over the three seasons. Eventually, we focused
238 on presence-absence data averaged over the three seasons only, due to higher uncertainty (e.g.
239 due to sampling error and seasonality) associated with the other data subsets. The results were

240 projected on maps by colouring the ERs and river types according to the percentage of
241 sensitivity species ($MSS < 0$) present. To construct the maps, we downloaded a map of the
242 world from the Natural Earth website ([https://www.naturalearthdata.com/downloads/10m-](https://www.naturalearthdata.com/downloads/10m-cultural-vectors/)
243 [cultural-vectors/](https://www.naturalearthdata.com/downloads/10m-cultural-vectors/)). The shape files for the ERs were obtained from the European Environment
244 Agency (<https://www.eea.europa.eu/data-and-maps/data/ecoregions-for-rivers-and-lakes>), and
245 their projection was transformed to match the projection of the world map using the
246 *spTransform* function from the **sp** package (version 1.3-1, Pebesma & Bivand, 2005).
247 Coordinates of all the RIVPACS sites were available in the RIVPACS database.

248 2.3. Statistics

249 A Kruskal-Wallis Rank Sum Test was done to check if there were any statistically significant
250 differences in sensitivity between ERs or RIVPAS groups. If this was true, multiple
251 comparisons of all the groups were done with Kruskal Wallis using the *kruskal* function from
252 the **agricolae** R package (version 1.2-8, Mendiburu, 2017). Fisher's least significant
253 difference criterion was used as a post-hoc test, and we used the Bonferroni correction as p-
254 adjustment method.

255

256 **Table 1.** Division of the 685 reference sites into the 7 super-groups, along with a description
257 of the dominant characteristics of the super-groups (taken from Davy-Bowker et al., 2008).

RIVPACS super-group	N sites	Dominant characteristics
1	64	All in Scotland, mostly islands
2	148	Upland streams, mainly in Scotland and Northern England
3	169	Intermediate rivers, South-East Scotland, Wales, North and South-West England
4	48	Small steeper streams, within 13 km of source
5	115	Intermediate size lowland streams, including chalk, South-East England
6	84	Small lowland streams, including chalk, South-East England
7	57	Larger, lowland streams, South-East England, larger, finer sediments

258

259 **3. Results**

260 3.1. Sensitivity models

261 Incorporating taxonomic relatedness slightly improved the predictive capacity of models for
262 invertebrate sensitivity towards narcotic and AChE inhibiting chemicals (higher adjusted R^2),
263 compared to models without taxonomy (Table 2). Interestingly, the trait ‘mode of respiration’
264 was incorporated in the taxonomy & traits model of narcosis (Figure A.3) and was also
265 present in the traits-only model. For AChE inhibition, mode of respiration was included in the
266 taxonomy & traits model (Figure A.4), but not in the traits-only model. Considering the
267 taxonomic predictors, V14, V2 and V4 were present in both the taxonomy-only and the
268 taxonomy & traits model for narcosis. For AChE inhibition, the predictors V7 and V3 were
269 present in both the taxonomy-only and the taxonomy & traits model.

270

271 **Table 2.** Predictive models constructed for narcotic and AChE inhibiting chemicals, in- and
 272 excluding taxonomy. Taxonomic predictors are indicated with a V. See Figures A.3 and A.4
 273 for a visualization of the predictors incorporated in the taxonomy & traits models.

MOA	Type of model	Model	Adj. R ²	p - value
Narcosis	Taxonomy & traits	MSS = -0.44 + 1.63 * V14 - 1.95 * V2 + 0.32 * respiration mode + 1.27 * V4	0.47	< 0.001
	Taxonomy-only	MSS = 0.16 + 1.66 * V4 + 1.64 * V14 + 1.16 * V5 - 1.14 * V2	0.42	< 0.001
	Traits-only	MSS = 0.04 - 0.25 * dispersal mode + 0.39 * respiration mode	0.20	0.011
AChE inhibition	Taxonomy & traits	MSS = 0.74 + 2.94 * V7 - 1.62 * V3 - 1.04 * V13 - 0.29 * respiration mode	0.62	< 0.001
	Taxonomy-only	MSS = 0.19 + 2.61 * V7 + 0.9 * V10 - 0.88 * V1 - 0.86 * V3	0.61	< 0.001
	Traits-only	MSS = 6.93 - 0.84 * life cycle duration - 1.13 * cycles per year - 0.17 * feeding mode - 0.78 * temperature preferendum	0.4	0.004

274

275 Cross-validation of the model species resulted in the correct classification of 82% and 74% of
 276 the genera as sensitive or tolerant for respectively narcosis and AChE inhibiting chemicals
 277 (Figure 1). For narcosis, the Diptera *Paratanytarsus* and *Mochlonyx*, the Odonata
 278 *Ophiogomphus*, the Ephemeroptera *Siphonurus*, the Gastropoda *Aplexa*, and the Annelida
 279 *Chaetogaster* were misclassified (predicted on the wrong side of the zero line). For AChE

280 inhibition, incorrect predictions were made in only two taxonomic groups, the Diptera
 281 *Glyptotendipes*, *Paratanytarsus*, *Tanytarsus*, and the Odonata *Anax*, *Crocothemis*,
 282 *Ophiogomphus* and *Orthetrum*.

283
 284 **Figure 1.** Observed MSS values (filled squares) and values predicted (unfilled circles) using
 285 traits and taxonomy according to the best models for (a) narcotic (b) and AChE inhibiting
 286 chemicals.

287 3.2. European freshwater ecoregions

288 3.2.1. Data availability.

289 For the ER communities, taxonomic data was available for 97% of the species, and covered
 290 four crustacean orders (Amphipoda, Anostraca, Decapoda, and Isopoda), and six insect orders
 291 (Coleoptera, Diptera, Ephemeroptera, Lepidoptera, Plecoptera and Trichoptera). Figure A.5
 292 shows the taxonomic composition of all ERs at the order level. For 19% of these species there
 293 was no or incomplete trait data available, leading to the exclusion of these species from our
 294 analysis. Of the remaining species, only around 5% had toxicity data available. We therefore

295 had to predict the sensitivity of around 95% of the species for which no toxicity data was
296 available using the taxonomy & traits models for narcosis and AChE inhibition.

297 3.2.2. Taxonomic pattern.

298 On the continental scale, 46 and 33% of the species were found sensitive ($MSS < 0$) towards
299 narcotic and AChE inhibiting chemicals, respectively. For narcotic chemicals, 18 families
300 contained only genera predicted as sensitive. Among these 18 families were all families
301 belonging to the order of Isopoda (1 family), as well as a part of the Amphipoda (1 family),
302 Plecoptera (6), and Trichoptera (10) families included in our study (Table A.1). Five families
303 contained both sensitive and tolerant genera. Four of these families belonged to the order of
304 the Trichoptera, and one to the order of Lepidoptera. The remaining 25 families were
305 predicted to only contain tolerant genera ($MSS > 0$), and included all of the families
306 belonging to the order of Anostraca (1 family), Decapoda (5), Diptera (1), and Ephemeroptera
307 (12), as well as the remaining Amphipoda (2 families), Plecoptera (1), and Trichoptera (3)
308 families included in this study (Table A.2).

309 For AChE inhibiting chemicals, there was little variation in sensitivity of the genera
310 belonging to the same family, and the whole family was either predicted to contain only
311 sensitive ($MSS < 0$) or only tolerant ($MSS > 0$) genera. All genera belonging to the order of
312 the Trichoptera and all genera belonging to the family of the Gammaridae were predicted as
313 sensitive (Table A.3), while all other families included in this study were predicted to contain
314 only tolerant genera (Table A.4).

315 3.2.3. Geographical pattern.

316 For both MOAs, we noticed that the South of Europe (e.g. ER 1) has the highest proportion of
317 sensitive species ($MSS < 0$), whilst Iceland (ER 19) is the ecoregion containing the lowest
318 proportion of sensitive species (Figure 2). Central Europe (e.g. ER 14) contains the lowest

319 percentages of sensitive species. ER 6 contains the largest percentage (57%) of species
320 sensitive to narcotic chemicals, whilst ER 24 contains the largest percentage (45%) of species
321 sensitive to AChE inhibiting chemicals.

322 When comparing the assigned sensitivity class of each ER for the two MOAs, we find that 8
323 of the 25 ERs were grouped into the same class for both MOAs (ER 1, 3, 5, 11, 18, 19, 21, 24,
324 Figure A.5). ER 2, 4, and 6 -10 were classified one or two classes lower for sensitivity
325 towards AChE inhibiting chemicals compared to sensitivity towards narcotic chemicals,
326 whilst the opposite was true for ER 12 -17, 20, 22, 23, and 25 (Figure A.6).

327

328 **Figure 2.** Percentage of sensitive taxa (MSS < 0) to narcotic (a) and AChE inhibiting (b) chemicals in European freshwater ecoregions. The
 329 numbers refer to the ecoregion number (ER 1 through ER 25).

330 3.3. RIVPACS river types

331 3.3.1. Data availability.

332 For the RIVPACS end-group communities, taxonomic data was available for 98% of the
333 species. To ensure that model predictions did not trespass the taxonomic range on which the
334 model was calibrated, any phylum that was not represented by one of the model species was
335 removed from the analysis. Consequently, sensitivity towards narcotic chemicals was
336 predicted for genera belonging to the phyla Annelida, Mollusca, and Arthropoda, whilst
337 sensitivity towards AChE inhibiting chemicals was predicted only for Arthropoda.
338 Coincidentally, in case of both datasets (Annelida, Mollusca, and Arthropoda, versus
339 Arthropoda only), 34% of the species had no or incomplete traits data available, leading to the
340 exclusions of these species from the analysis. Of the remaining species, less than 10% had
341 toxicity data available. We therefore had to predict the sensitivity of 90% of the species for
342 which no toxicity data was available using the taxonomy & traits models for narcosis and
343 AChE inhibition.

344 3.3.2. Taxonomic pattern.

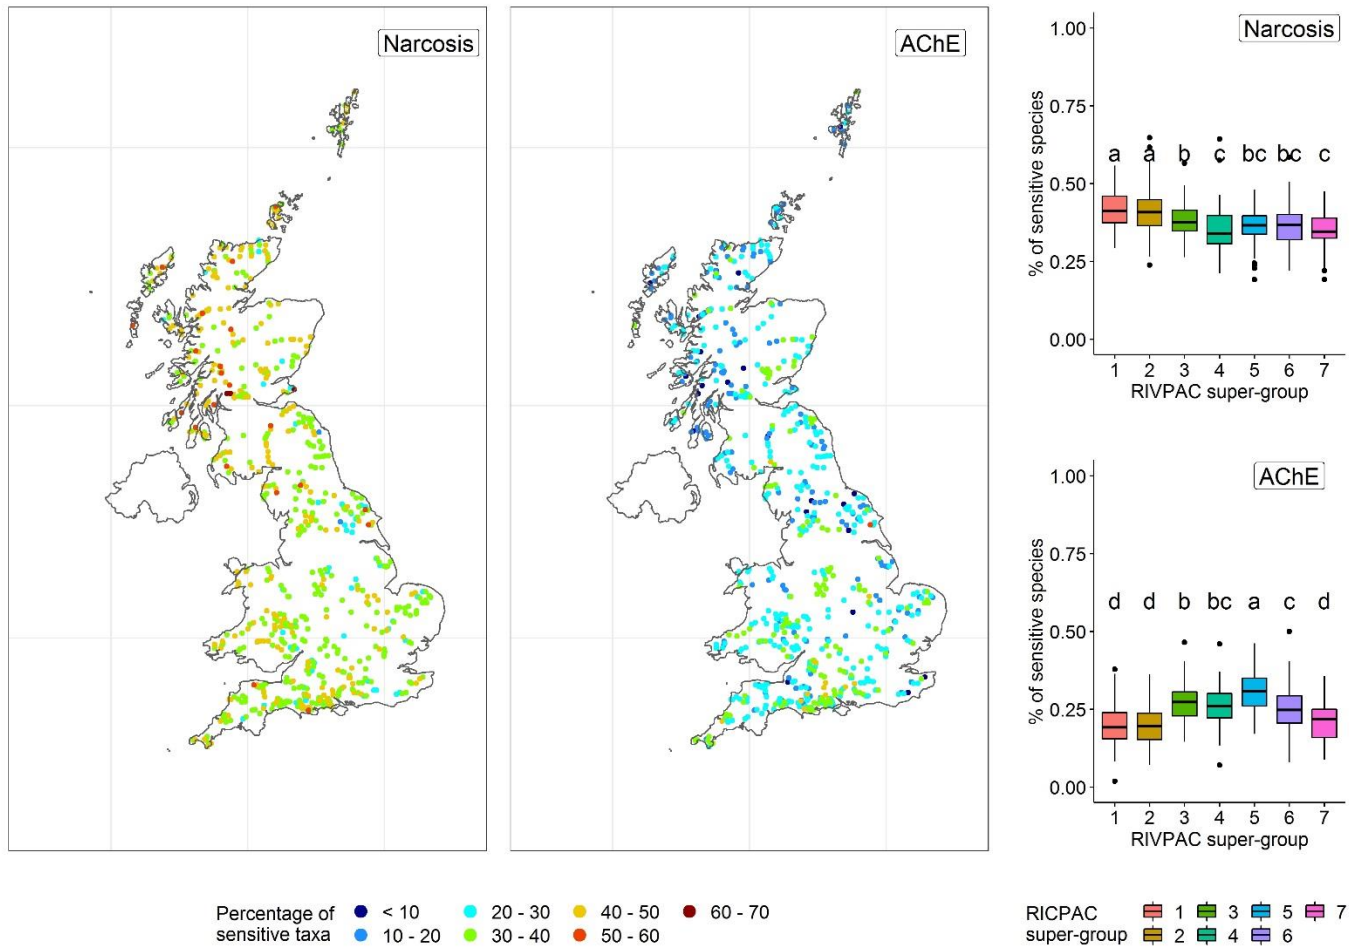

345 Within the UK, 38, and 25% of the species were found sensitive ($MSS < 0$) to narcotic and
346 AChE inhibiting chemicals respectively. For narcotic chemicals, 37 families contained only
347 genera predicted as sensitive, with an MSS value below zero. Among these 37 families were
348 all families belonging to the order of Annelida (9 families), Isopoda (1), and Odonata (7), as
349 well as a part of the Amphipoda (1), Plecoptera (6), Trichoptera (8), and Gastropoda (5)
350 families included in our study (Table A.5). Four families contained both sensitive and tolerant
351 genera, all of them belonging to the order of Trichoptera. The 49 remaining families were
352 predicted to only contain tolerant genera, with an MSS value above zero. Among them were
353 all families belonging to the order of Arguloidea (1 family), Coleoptera (7), Decapoda (1),

354 Diptera (5), Ephemeroptera (9), Hemiptera (7), Lepidoptera (1), Megaloptera (1), Neuroptera
355 (2), and Bivalvia (4), as well as the remaining Amphipoda (3), Plecoptera (1), Trichoptera (3),
356 and Gastropoda (4) families (Table A.6).

357 For AChE inhibiting chemicals, there was little variation in sensitivity of the genera
358 belonging to the same family, and, as for the ER assemblages, the whole family was either
359 predicted to only contain sensitive ($MSS < 0$) or tolerant ($MSS > 0$) genera. In total, 25
360 families contained genera that were all predicted as sensitive. This encompassed all families
361 belonging to the order of Trichoptera (15 families), as well as a part of the Amphipoda (1),
362 Diptera (2), Neuroptera (1), and Odonata (6) families (Table A.7). The remaining 43
363 Arthropod families were predicted to only contain tolerant species, and included all Arguloidea
364 (1 family), Coleoptera (7), Decapoda (1), Ephemeroptera (9), Hemiptera (7), Isopoda (1),
365 Lepidoptera (1), Megaloptera (1), and Plectoptera (7), as well as the rest of the Amphipoda (3),
366 Diptera (3), Neuroptera (1), and Odonata (1) families (Table A.8).

367 3.3.3. Geographical pattern.

368 Considering the RIVPACS sites, geographical patterns show opposite results for the two
369 MOAs (Figure 3). Regions containing more species sensitive towards narcotic chemicals were
370 observed in the west and north of the UK, while regions containing more species sensitive
371 towards AChE inhibiting chemicals were found in the south, south-west of the UK (Figure 3).
372 RIVPACS sites located in small to intermediate lowland streams contained more sensitive
373 species towards AChE inhibiting chemicals (super-groups 3, 4 and primarily 5, boxplots
374 Figure 3), whilst for narcotic chemicals most sensitive species were found at sites located in
375 upland rivers, mainly located in Scotland and Northern England (super-groups 1 and 2,
376 boxplots Figure 3). For both MOAs, larger, lowland streams located in South-East England
377 (super-group 7), contained the smallest percentage of sensitive species.

378

379 **Figure 3.** Map of the UK showing the percentage of sensitive taxa (MSS < 0) present at all
 380 RIVPACS sites, and boxplots of the percentage of sensitive species (MSS < 0) present in each
 381 RIVPACS super-group to narcotic and AChE inhibiting chemicals. Letters in boxplots
 382 indicate significant differences (p < 0.05).

383 4. Discussion

384 4.1. Traits and taxonomic predictor selection, and how this can be improved

385 For both MOAs, mode of respiration was selected as an important trait for explaining species
 386 sensitivity (Table 2). Several studies have investigated the relationship between respiration
 387 and AChE inhibiting chemicals before (Buchwalter, Jenkins, & Curtis, 2002; Rico & Van den
 388 Brink, 2015; Rubach et al., 2012; Rubach et al., 2010; van den Berg et al., 2019), and have
 389 frequently found respiration important for determining species sensitivity, primarily due to an

390 influence of respiration mode on uptake rates. The relationship between narcosis and
391 respiration has been studied less, and there is to our knowledge only one study available that
392 performed an analysis with narcotic chemicals (van den Berg et al., 2019). The result of that
393 study closely aligns with ours, undoubtedly due to the large overlap in the data included in
394 both studies.

395 We find that combining traits with taxonomic information results in models with increased
396 predictive power, although only marginal (Table 2). Previous studies likewise emphasize the
397 importance of complementing traits approaches with taxonomic approaches (Pilière et al.,
398 2016; Poff et al., 2006; Poteat et al., 2015). For example, Pilière and colleagues (2016) used
399 boosted regression tree modelling to assess the environmental responses of single traits,
400 orders and trait profile groups. They found that taxa belonging to the same trait profile group
401 but to different orders showed different environmental responses. Similarly, they found that
402 taxa belonging to the same order but to different trait profile groups showed different
403 environmental responses (Pilière et al., 2016). This indicates that unique information related
404 to the evolutionary history was captured by the order of a taxon, whilst another part was
405 captured by the trait set of a taxon. We find a similar result in our study, where the taxonomy-
406 only model explaining sensitivity towards narcotic chemicals has an explanatory power of
407 0.42. This explanatory power increases to 0.46 when traits are included (Table 2). For AChE
408 inhibition we see a similar result, although there the increase is only from 0.61 to 0.62 (Table
409 2). Although the increase of predictive power is only slight, the increase in mechanistic
410 explanation is large, since the traits reveal mechanistic information regarding species
411 sensitivity, and the taxonomic predictors point out taxa which show a different response to the
412 chemical. The taxonomic predictors can thereby focus future research on finding the actual
413 mechanisms that are different between these taxa. For this reason, both traits and taxonomy
414 should be taken into consideration simultaneously for maximum benefit to risk assessment.

415 Although our models already show a good fit on the available data (Table 2), we anticipate
416 that technological advances both in molecular and computational technologies will lead to an
417 improvement of our models over time. Applying sophisticated molecular approaches can help
418 with resolving the taxonomy of currently still problematic organism groups, for instance, by
419 increasingly basing taxonomy on DNA markers, ideally replacing taxonomy completely by
420 phylogenetics in due time (Hebert, Cywinska, Ball, & Dewaard, 2003). Additionally, basing
421 phylogenetic trees on key target genes associated with Adverse Outcome Pathways (AOPs)
422 might substantially improve phylogenetic predictive models for application in ecotoxicology
423 (e.g. LaLone et al., 2013). Furthermore, our models could improve with increased computing
424 power. Due to memory limitations and the structure of currently existing model selection
425 algorithms, we had to restrict the number of predictors going into the model selection process.
426 However, since we maintain strict rules to avoid overfitting (e.g. the use of AICc as a model
427 selection criterion and the use of a multivariate approach for the taxonomic predictors), it
428 would be possible to add more predictors to the model without increasing the chance of
429 overfitting.

430 4.2. Sensitivity patterns at European scale

431 At the continental scale, we predict that around half of the species are sensitive ($MSS < 0$)
432 towards narcotic chemicals. This matches our expectations, since MSS is a relative value, and
433 there is not any taxonomic group known that is particularly sensitive towards narcotic
434 compounds (Escher & Hermens, 2002). For AChE inhibiting chemicals we predict around
435 one third of the arthropod species to be sensitive ($MSS < 0$). This is less than found in the
436 sensitivity ranking of Rico and Van den Brink (2015), where on average 70% of the
437 Arthropoda were found sensitive towards AChE inhibiting chemicals (organophosphates and
438 carbamates). However, this difference likely originates from the fact that Rico and Van den
439 Brink (2015) also included non-arthropod species. Since MSS is a relative value, and

440 arthropod species are the most sensitive group towards AChE inhibiting chemicals, including
441 non-arthropod species will result in relatively more sensitive arthropod species.

442 Considering both MOAs, our predictions show that river basins in central Europe contain
443 fewer sensitive species than those situated in the south (Figure 2). We reason that this results
444 from, on the one hand, chemical exposure patterns before and during the period that Illies
445 recorded the community composition of the ERs (Illies, 1978), and on the other hand, from
446 more ancient phylogeographical and ecological processes. Indeed, the pattern we find
447 coincides with the emission pattern of multiple persistent organic contaminants commonly
448 used in the 1960s, around the time when Illies was constructing his species database (Illies,
449 1978). Chemicals like DDT (Dichloro-diphenyl-trichloroethane, Stemmler & Lammel, 2009),
450 lindane (Prevedouros, MacLeod, Jones, & Sweetman, 2004), mercury (Pacyna, Pacyna,
451 Steenhuisen, & Wilson, 2003), and PCDFs (polychlorinated dibenzofurans, Pacyna, Breivik,
452 Münch, & Fudala, 2003) were more extensively used in central Europe, potentially reducing
453 the occurrence of more sensitive species in those regions. However, we think that chemical
454 exposure was not the main determinant for species composition, primarily because Moog and
455 colleagues demonstrated that different ERs could always be differentiated from each other
456 based on their community composition, even when heavily impacted by chemical stress
457 (Moog, Schmidt-Kloiber, Ofenböck, & Gerritsen, 2004). Therefore, we argue that the main
458 cause for the geographical pattern we see lies in the phylogeography of Europe, in which
459 extreme climatic events wipe out more sensitive species, and mountainous regions
460 consecutively serve as refugia and biodiversity hotspots (Rahbek, Borregaard, Antonelli, et
461 al., 2019; Rahbek, Borregaard, Colwell, et al., 2019). During the last ice age, glaciers covered
462 the majority of northern Europe, forcing most species towards refugia present in southern
463 Europe or to ice free parts of high mountain areas (e.g. Schmitt & Varga, 2012). Indeed, there
464 is a large overlap in biodiversity hotspots (Médail & Quézel, 1999; Mittermeier, Myers,

465 Thomsen, Da Fonseca, & Olivieri, 1998; Rahbek, Borregaard, Colwell, et al., 2019) or so-
466 called regions of large endemism (Deharveng et al., 2000), with regions containing the
467 highest percentage of sensitive species (Figure 2). Then after the last ice age, species
468 recolonized northern Europe from these southern refugia, which is confirmed by the fact that
469 almost all species occurring in northern European are also present in central and/or southern
470 Europe (Hering et al., 2009). The relatively higher sensitivity of ER 22 and 15 (especially
471 towards AChE inhibiting chemicals, Figure 2) can be explained due to migration of more
472 sensitive species from Siberian refugia, e.g. located in the Ural mountains (Bernard, Heiser,
473 Hochkirch, & Schmitt, 2011; Schmitt & Varga, 2012).

474 4.3. Sensitivity patterns at UK scale

475 We see that certain biases in the underlying data are revealed in the sensitivity patterns we
476 find for the UK. For instance, at a national scale, fewer species were considered sensitive
477 compared to the continental scale, both towards narcotic and AChE inhibiting chemicals. We
478 think this is caused by the interaction of two things. First, our models are biased in predicting
479 entire families as sensitive or tolerant, in some cases resulting in entire phyla being predicted
480 as sensitive or tolerant. Second, the RIVPACS communities are taxonomically uneven at
481 genus level, the level we used to predict species sensitivity. Indeed, dipterans make up around
482 40% of all genera present which all are predicted to be tolerant towards the two MOAs. In this
483 case, the taxonomic unevenness *at genus level* specifically, has a large influence on the
484 percentage of species sensitive at the national scale. When we compare the ER and RIVPACS
485 results at the family level, results between the two datasets are more consistent. For instance,
486 for the ER dataset we predict that 33, 59, and 86% of respectively Amphipoda, Trichoptera,
487 and Plecoptera families were sensitive towards narcotic compounds. This was 25, 53, and
488 86% of the families in the same orders in the RIVPACS dataset.

489 The geographical distribution of sensitive species throughout the United Kingdom is less
490 pronounced than at a European level, although the opposing results of the RIVPAC super-
491 groups towards the two MOAs studied is striking. This contradictory result corresponds with
492 the study of Van den Berg et al. (2019), where an inclusive database approach reveals large
493 differences in species sensitivity depending on MOA. Their study shows that AChE and
494 narcosis are on opposing ends of a dendrogram clustered on a matrix of species sensitivity
495 towards six diverse MOAs, indicating that AChE and narcosis show the largest differences in
496 species sensitivity among all MOAs tested. Additionally, we found alternative explanations
497 that could explain the contradicting geographical patterns we found for the two MOAs.

498 As an explanation for the geographical pattern for narcotic compounds, we find a large
499 overlap between hotspots of sensitivity towards narcotic toxicants and conservation areas in
500 the UK (e.g. with Special Areas of Conservation, Special Protection Areas, Sites of Special
501 Scientific Interest, (Gaston et al., 2006)). It is known that protected areas serve as
502 establishment centres, enabling the colonization of new regions by species that are shifting
503 their geographical ranges (Hiley, Bradbury, Holling, & Thomas, 2013; Thomas et al., 2012).
504 Although all RIVPACS sites are considered reference sites and have been selected because of
505 low anthropogenic influence, our results show that whether or not these sites are included or
506 in close proximity to a conservational area leads to a higher support of sensitive species,
507 likely due to an increased landscape and habitat heterogeneity.

508 As an explanation for the geographical pattern for AChE inhibiting compounds, the larger
509 differences between the sensitivity of super-groups towards AChE inhibiting chemicals
510 demonstrates that species sensitive towards AChE inhibition were more differentiated
511 according to river type (i.e. the abiotic preferences of the species) than according to the
512 availability of conservation areas. Additionally, the finding that the North to South pattern
513 that we found at a European level was not noticeably present at the UK level is probably due

514 to smaller differences in environmental factors (e.g. temperature, precipitation,
515 phylogeographic history) when considering the UK only, compared to when the whole of
516 Europe is considered.

517 4.4. Implications and outlook

518 Our analysis indicates that not only the taxonomic resolution of available trait databases is
519 crucial, also the resolution of the model is important. Additionally, we are confident that our
520 models will improve in the near future, for instance by the replacement of the taxonomic tree
521 with a phylogenetic tree based on validated biomarkers (for instance, as in Simões et al.,
522 2019). In that case, the successful application of our suggested approach is mainly limited by
523 access to raw biological data (e.g. species abundance), which is currently still problematic
524 because governmental agencies provide ecological status information based on general
525 indices rather than species counts. Providing access to raw data, along with clear metrics on
526 the quality of that data (e.g. meeting the criteria defined in Moermond, Kase, Korkaric, &
527 Ågerstrand, 2016), would foster our understanding of the links between anthropogenic
528 stressors and populations or communities. Subsequently combining this effect data with
529 chemical concentration data would be the next logical step, and would require chemical
530 concentration data on all chemicals that are being monitored, not only priority substances, to
531 be made widely available by governmental agencies.

532 The current analysis provides an important new chapter in the development of environmental
533 scenarios that can be used for the environmental risk assessment of chemicals at larger
534 geographical scales (Franco et al., 2016; Rico et al., 2016). Our work is the first attempt to
535 apply sensitivity models on community assemblage data previously grouped according to both
536 biotic and abiotic parameters (e.g. invertebrate community composition, water depth,
537 alkalinity and temperature, Davy-Bowker et al., 2008). This combination of both biological

538 and spatial data is required to successfully characterize exposure, effects and recovery of
539 aquatic non-target species under realistic worst-case conditions. Currently, mismatches exist
540 between parameter values and spatial-temporal scales of ecological models used to predict
541 potential effects of chemicals (Rico et al., 2016). Our approach contributes to solving this
542 mismatch by simultaneously incorporating biological and environmental factors.

543 In addition to this, the inclusion of traits in our models leads to an increased mechanistic
544 understanding of cause-effect relationships, and allows for the application across wide
545 biogeographical regions. This extrapolation enables, for instance, the comparison of
546 ecological status across countries or regions that have so far remained unmonitored due to
547 practical reasons (e.g. remote regions), for instance, by using species assemblages predicted
548 by means of species distribution models (e.g. as in He et al., 2015). Also, patterns across wide
549 geographical scales can easily be compared with other studies by means of geographical
550 information systems (GIS) and simple additive models to reveal regions where multiple
551 stressors might be causing an effect simultaneously (e.g. as in Figure A.6, and see Vaj,
552 Barmaz, Sørensen, Spurgeon, & Vighi, 2011 for an example study). Take, for instance, the
553 potential impact of climate change on aquatic insects. Hering et al. (2009) show that southern
554 European regions contain the highest fraction of species sensitive towards climate change.
555 Since this largely overlaps with the regions we found to be most sensitive towards chemical
556 stressors (Figure 2), there might be an increased overall effect on aquatic communities due to
557 an unexpected interaction between climate change and chemical stress. In the north-east of
558 Europe, a similar amplification effect may occur due to an overlap in regions with a relatively
559 high chemical sensitivity (Figure 2), and predicted increased potential of harmful arthropod
560 pest invasions (Bacon, Aebi, Calanca, & Bacher, 2014).

561 Finally, our study demonstrates that sensitivity towards chemical stressors is spatially
562 variable, and that although entire regions can be considered relatively tolerant, there might

563 still be certain river reaches with a large percentage of sensitive species. Applied at relevant
564 geographic scales, the methodology described in this study has demonstrated the potential to
565 identify hotspots of sensitive species for given chemical classes. When applied to current risk
566 assessment approaches, this will both increase the biological realism of assessments, and
567 reduce the need for overly conservative assessment factors.
